## **Abstract**

In this paper, we present a full-scale analysis on the risks of disrupting U.S. supply chains by an operational hazard like the extremely cold weather event in January 2014 provided in a Kaggle dataset that was composed of 1,000 transactions with 24 qualitative and quantitative attributes.

After the dataset was validated for completeness and consistency, exploratory data analysis and statistical inference methods, such as Z-tests, T-tests, One-Way and Two-Way ANOVA, Chi-Square tests, and regression modeling, were conducted using Python, Excel, and R. It is shown that most perturbations are non-existent or the result of under supply and inclement weather, and there are no statistically significant differences in energy utilization, supplier dependability, or order values between shipping modes, risk groups, or disruption seriousness.

The regression also shows that the influential variables of quantity ordered, communication cost, supplier reliability, and disruption history cannot significantly explain variability in order of value. In sum, these results indicate that the supply chain system modeled in this data set has a steady operating character with little statistical difference across the groups, suggesting that additional unobserved or external influences may be driving shipment risk and value results. These findings also may help inform the U.S. defense logistics community in enhancing risk management, in focusing data-sharing efforts, and in advancing resilience planning.

## **Introduction**

Stable U.S. supply chains are essential for everything, including healthcare and manufacturing, technology, and food distribution. These interlinked systems have been subjected to increasing strains in recent years, with disruptions to logistics, suppliers, and external shocks originating from geopolitical, environmental, and pandemic incidents. Successfully navigating such complex risks is critical, not only to ensure that operations continue to run smoothly, but also that the entire economy can withstand shocks.

In this paper, we provide a full-scale data driven analysis on a real-world U.S. supply chain data set from Kaggle, which includes 1,000 transaction records and 24 features both qualitative and quantitative in nature. The main purposes are: (i) to detect the influencing factors with the greatest correlation with the shipment risk and analyze supplier and buyer behavior under diverse operational situations, and (ii) to identify trends in the frequency and severity of interruptions.

Using Python, Excel, and R, descriptive statistics and exploratory data visualization techniques are used to analyze delivery delays, supplier reliability, disruption types, energy consumption, and mode of shipment. In so doing, the report seeks to provide insight that the U.S. defense logistics community can use to improve risk management and supply chain performance in a highly complex U.S. logistics environment.

## **Dataset Definition and Description**

This study is based on "U.S. Supply Chain Risk Analysis," a dataset that includes transactional data that simulates real supply chain activities. The data set contains 1,000 unique observations on 24 variables, giving a rich mixture of qualitative and quantitative measures. These variables represent the entire process of an order from ordering to delivery, including risk and performance measures.

The dataset comprises both qualitative (15) and quantitative (9) variables. It represents supplier-buyer interactions, orders, disruptions, and model optimization of metrics.

### **Quantitative Variables:**

Quantity Ordered, Order Value (USD), Communication Cost (MB), Energy Consumption (Joules), Historical Disruption Count, Supplier Reliability Score, Available Historical Records, Federated Round, Parameter Change Magnitude.

### **Qualitative Variables:**

Order ID, Buyer ID, Supplier ID, Product Category, Shipping Mode, Delay Days, Disruption Type, Disruption Severity, Organization ID, Data Sharing Consent, Dominant Buyer Flag, Supply Risk Flag, Order/Dispatch/Delivery Dates.

## **Pre-Cleaning Dataset Variable Summarization**

The dataset was observed to be tidy and non-redundant with no missing records before data preprocessing.

### **Categorical Variable Summary**

Some relevant operational insights can be observed from the frequency tables of essential categorical variables.

**Product Category:** The number of orders is balanced between categories; there are slightly more orders in Electronics (210) and Textile (206).

**Shipping Mode:** The shipments were uniformly distributed over the modes of shipment, Air (263) being the predominant one.

**Disruption Type:** A large share of shipments (486) was undisrupted. When they did, the leading causes were short supply (135) and weather (133).

**Supply Risk Flag:** Most shipments (514) are tagged as risk, emphasizing that risk is a salient feature in this supply chain ecosystem.

**Data Sharing Consent:** Most suppliers (805) opt to share data, which bodes well for collaborative analytics.

## Quantitative Variable Summary

**Central Tendency of Quantitative Variables:** We utilized Excel to obtain the descriptive statistics for the US Supply Chain Risk Analysis dataset. R and Python were used to further explore and confirm the descriptive statistics. The descriptive statistics of our numerical variables (Quantity Ordered, Order Value, Communication Cost, Energy Consumption, Historical Disruption Count, Supplier Reliability Score, Available Historical Records, Federated Round, and Parameter Change Magnitude) are represented in Table 1 highlighting Mean, Median, Range (Minimum and Maximum values), IQR, Lower and Upper Bounds, Standard Deviation, and Q1 and Q3. A complete view of descriptive statistics is displayed in Table 1.

**Dispersion of Quantitative:** When reviewing our variables, we can see that Quantity Ordered, Energy Consumption, Supplier Reliability Score, and Parameter Change Magnitude are slightly skewed right. Variables of Order Value, Communication Cost, Historical Disruption Count, Available Historical Records, and Federated Round are slightly left skewed. All nine numerical variables in the dataset have skew values very close to zero ranging from  $-0.070$  to  $0.0415$ , suggesting the dataset is nearly symmetric with no strong pull from extreme low or high values. The kurtosis values of all nine variables lie between  $1.76$  and  $1.90$ , making our data set platykurtic, which means having light tails and very few extreme outliers. For a full, detailed restatement of the descriptive statistics, please see Table 1.

**Table 1: Data Summary of Numerical Variable**

| <b>Measures</b>           | <b>Quantity ordered</b> | <b>Order value (USD)</b> | <b>Communication cost (mb)</b> | <b>Energy consumption (Joules)</b> | <b>Historical disruption count</b> | <b>Supplier reliability score</b> | <b>Available historical records</b> | <b>Federated round</b> | <b>Parameter change magnitude</b> |

## Cleaning Steps Details

Prior to analysis, the dataset was thoroughly checked for quality-related issues, including completeness and format consistency. The review revealed that the dataset was exceptionally clean and uniform.

**Missing values:** we checked all 24 columns for any null or missing values. The data was complete; no entry was missing.

**Duplicated rows:** Check if there are any duplicated rows in the data set. This testifies to the nonexistence of duplicated records.

**Format and special characters:** All the categorical and string-based columns were checked for inconsistencies, e.g. leading or trailing spaces or special characters. None was found. None were encountered.

**Outlier Detection:** The lower and upper limit for the quantitative data variables were calculated by using the IQR method for identifying the statistical outliers. A few points did lie beyond these bounds, but as contextualized review, they were not seen as erroneous but indeed seemed like operational plausible extremes rather than simple data entry error. Hence, we keep all points. All data points were retained.

As the original data was already of high quality, no clean-up or transformation of the data was necessary. The analysis was carried out on raw data.

## Post-Cleaning Dataset Variable Summarization

Since no changes were introduced into the dataset in the quality of data verification procedure, the summarization of the dataset variables after cleaning is the same as the pre-cleaning summaries given in Pre-cleaning.

## Tests

### Z-Test

#### One-Tailed Z-test for order value

**Alternate Hypothesis ( $H_1$ ):** The average order value for the Electronics product category is significantly higher than the overall average order value.

**Null Hypothesis ( $H_0$ ):** The average order value for the Electronics product category is not significantly higher than the overall average order value

**$H_0$ :**  $\mu_0 \leq \mu_1$        **$H_1$ :**  $\mu_0 > \mu_1$

#### Assumptions Testing:

**Normality Testing:** The average order value was determined to be 25,290 (USD). A Shapiro Wilk normality test<sup>1</sup> was conducted on R Studio version 2025.09.1+401 for the order value of electronic products. The normality test for the same returned  $W = 0.94774$ , and the p-value was  $6.666 \times 10^{-07}$  (as indicated in Figure 1 below), indicating non-normal data.

```
> Electro=filter(US_Supply_Chain,Product_Category=="Electronics")  
> shapiro.test(Electro$Order_Value_USD)
```

```
Shapiro-Wilk normality test  
  
data: Electro$Order_Value_USD  
W = 0.94774, p-value = 6.666e-07
```

**Figure 1. Normality test result for Z Test variable from R- Studio**

**Transformation of the Order Value:** We then conducted logarithmic transformation using the Excel command (LOG10). The normality of order value post transformation returned  $W = 0.81657$ ; the corresponding p-value was  $5.338 \times 10^{-15}$  indicating non-normal data.

We conducted the Z test assuming that the data was normal. The Z score of Order Value resulted in 1.8144. *(Please refer to appendix K, Figure 12 for logarithmic transformation)* The p-value corresponding to z-statistic of the Order value of the electronics is 0.03481.

In a nutshell, we understand that **at the 1% level**, results are **not** statistically significant. We do not have enough evidence to conclude the true mean is greater than 25,290. **At the 5% level and 10% level**, results **are** statistically significant. We conclude that the average order value for the Electronics product category is **not significantly higher** than the overall average order value. *(Please refer to appendix K, Figure 14 for Z- test results computed using R).*

## T-Test

### Two-sample T-test for Supply Risk Flag and Supplier Reliability Score.

**Alternate Hypothesis ( $H_1$ ):** Suppliers with supplier risk flag 0 have significantly higher reliability scores.

**Null Hypothesis ( $H_0$ ):** Suppliers with supplier risk flag 0 do not have significantly higher reliability scores.

**$H_0: \mu_0 = \mu_1$        $H_1: \mu_0 > \mu_1$**

### Assumptions Testing:

**Normality Testing:** The low and high-risk reliability scores were considered to conduct the right-tailed t-test. This test for reliability scores resulted in  $W = 0.96024$  and  $W = 0.9482$ , p- value  $3.524 \times 10^{-10}$  and  $1.982 \times 10^{-12}$  for 0 and 1 reliability scores respectively, indicating non-normal data *(Please refer to Figure 2 below)*. Due to non-normal data, the logarithmic transformation was necessary to proceed further.

#### Shapiro-Wilk normality test

```
data: Low_risk$Supplier_Reliability_Score
W = 0.96024, p-value = 3.524e-10
```

#### Shapiro-Wilk normality test

```
data: High_risk$Supplier_Reliability_Score
W = 0.9482, p-value = 1.982e-12
```

**Figure 2. Normality test result for T-Test variables from R- Studio**

**Transformation of the Supplier Reliability Score variable:** We conducted the logarithmic transformation on Supplier Reliability Score using the Microsoft Excel function and command LOG 10 (*Please refer to Figure 15 in Appendix L*). As seen in Figure 16, the Shapiro Wilk normality test post logarithmic transformation resulted in  $W=0.9566$  and  $W=0.94442$  where p value is  $9.14 \times 10^{-11}$  which is less than 0.05, indicating non-normal distributions. However, we move forward assuming that data are normal.

**Homogeneity of Variance Test:** Levene's test for homogeneity of variances was conducted, using R version 2025.05.1+513. We find that at 5% significance level, the assumptions of equal variances between groups are met. (*Please refer to Figure 17 in Appendix L*)

As seen from *Appendix L*, Suppliers with low-risk flags have significantly higher reliability scores. The p-value is 0.9324, which is very high (much greater than the typical significance level of 0.05). Therefore, we conclude at all conventional significance levels (1%, 5%, and 10%), the p-value of 0.9324 is substantially larger than the threshold.

Therefore, there is no statistically significant evidence to conclude that the true difference in means between supplier risk flag 0 and supplier risk flag 1 is greater than 0 and Suppliers with supplier risk flag 0 do not have significantly higher reliability scores. The slight observed difference in sample means (0.7388 vs. 0.7523) is likely due to random chance. (*Please refer to appendix L, Figure 18 for T- test results computed using R*)

### **One-Way ANOVA Test**

**Alternate Hypothesis ( $H_1$ ):** Air, Road, and Rail shipping mode have similar energy consumption.

**Null Hypothesis ( $H_0$ ):** Air, Road, and Rail shipping mode do not have similar energy consumption.

## Assumption Testing

**Normality Testing:** The Shapiro-Wilk tests were run to check if the Energy\_Consumption\_Joules data is normally distributed within each Shipping\_Mode group from Figure 3, we get the p-value for Air is  $1.821 \times 10^{-07}$ , Rail is  $2.004 \times 10^{-06}$  and Road is  $1.289 \times 10^{-07}$  which are all significantly less than 0.05. This shows that the data for all three shipping modes is not normally distributed.

```
> Air=filter(US_Supply_Chain,Shipping_Mode=="Air")
> Rail=filter(US_Supply_Chain,Shipping_Mode=="Rail")
> Road=filter(US_Supply_Chain,Shipping_Mode=="Road")
> shapiro.test(Air$Energy_Consumption_Joules)

      Shapiro-Wilk normality test

data:  Air$Energy_Consumption_Joules
W = 0.95331, p-value = 1.821e-07

> shapiro.test(Rail$Energy_Consumption_Joules)

      Shapiro-Wilk normality test

data:  Rail$Energy_Consumption_Joules
W = 0.96076, p-value = 2.004e-06

> shapiro.test(Road$Energy_Consumption_Joules)

      Shapiro-Wilk normality test

data:  Road$Energy_Consumption_Joules
W = 0.95069, p-value = 1.289e-07
```

**Figure 3. Normality test result for One- way ANOVA variables from R- Studio**

**Transformation of the Supplier Reliability Score variable:** After finding the original Energy Consumption Joules was not normally distributed, applied a log transformation to see if that would normalize the data. However, the new Shapiro-Wilk test results on the log-transformed data from figure 6 still show p-values for Air is  $1.334 \times 10^{-07}$ , Rail is  $1.903 \times 10^{-09}$  and Road is  $1.121 \times 10^{-09}$  that are all significantly less than 0.05. This means the logarithmic transformation failed in making the data normal. *(Please refer to Figure 19 in Appendix M)*

**Homogeneity Of Variance:** The Levene's Test was performed to check if the variance of Energy Consumption Joules is equal across the different Shipping Mode groups. From *Figure 20, Appendix M*, the resulting p-value is 0.7233. Since this p-value is greater than 0.05, the variances are homogeneous, thus satisfying this assumption for testing.

The Standard One-Way ANOVA test is performed using **aov () command** in R (version 4.5.1), from Figure 8 we get the f value as 0.543, p-value is 0.582 is much greater than 0.05 show that there is no statistically significant difference in the mean Energy Consumption Joules across the different Shipping Mode groups. *(Please refer to Appendix M, figure 21).*

#### **Post-hoc Tuckey HSD Test:**

This output is the Tukey HSD post-hoc test, which was run after the ANOVA. The test compares all possible pairs of Shipping Mode groups *(please refer to Appendix M, figure 22)*. Crucially, all p-adjusted values are greater than 0.05 (the smallest is 0.609), confirming that no two individual shipping modes are statistically different from each other in terms of their mean Energy Consumption Joules.

#### **Two-Way ANOVA**

##### **Two- Way Anova for Shipping Mode, Disruption Severity and Energy Consumption:**

Shipping Mode and Disruption Severity are independent variables and Energy Consumption is the dependent variable

#### **Alternative Hypotheses:**

**$H_{11}$ : At least one mean energy consumption differs across shipping modes**

**$H_{12}$ : At least one mean energy consumption differs across disruption severity levels**

**$H_{13}$ : There is a significant interaction between Shipping Mode and Disruption Severity on Energy Consumption**

**Null Hypotheses:**

**$H_{01}$ : The energy consumption does not impact air, rail, road shipping modes.**

**$H_{02}$ : The energy consumption does not impact high and low disruption severities.**

**$H_{03}$ : There is no interaction effect between shipping mode and disruption severity on the energy consumption.**

**Assumptions Testing:**

**Normality Testing:** The means of energy consumption for air, rail and road shipping modes are 258.85, 269.6, 268.37, respectively. The means of energy consumption for high and low types of disruption severity is 290.19, 277.49, respectively. The Shapiro Wilk normality test was conducted on R Studio for shipping modes, disruption severity, and energy consumption. As seen in *figure 4* below, we find that p-value is less than 0.05. Based on p-value, we conclude that samples do not belong to a normally distributed population.

```
> Air=filter(df,Shipping_Mode=="Air")
> Rail=filter(df,Shipping_Mode=="Rail")
> Road=filter(df,Shipping_Mode=="Road")
> shapiro.test(Air$Energy_Consumption_Joules)

Shapiro-Wilk normality test

data:  Air$Energy_Consumption_Joules
W = 0.94615, p-value = 0.001319

> shapiro.test(Rail$Energy_Consumption_Joules)

Shapiro-Wilk normality test

data:  Rail$Energy_Consumption_Joules
W = 0.9511, p-value = 0.001589

> shapiro.test(Road$Energy_Consumption_Joules)

Shapiro-Wilk normality test

data:  Road$Energy_Consumption_Joules
W = 0.94124, p-value = 0.0003953
```

**Figure 4. Normality test result for Two- way ANOVA variables from R- Studio**

**Transformation of Energy Consumption Variable:** After applying logarithmic transformation for energy consumption and we repeated the Shapiro Wilk test. Even then p value is less than 0.05 (*please refer figure 23 in Appendix N*), meaning that the distribution is not normal. However, given the large sample size, we proceeded with the ANOVA under the assumption of approximate normality based on the Central Limit Theorem.

**Homogeneity of Variance Test:** We conducted Levene's test for equality of variances using R Studio version 4.5.1, to find if the variance of energy consumption joules is same between the combined groups of shipping mode and disruption type. After the test we found that the p-value is 0.232 (*please refer figure 24 in Appendix N*), which is more than the significance level of 0.05 and the assumption of homogeneity of variances is satisfied. (F value is 1.3801)

As assumptions are met, a standard two-way ANOVA test is performed. The two-way ANOVA produced an F-statistic of 0.032 ( $p = 0.968$ ) (*please refer figure 25 in Appendix N*), for shipping mode, 0.341 ( $p = 0.559$ ) for Disruption Severity, and 1.221 ( $p = 0.297$ ) for their interaction. Based on these results, we conclude that at the 1%, 5%, and 10% significance levels, the energy consumption joules do not differ significantly across shipping modes, disruption severities or their interaction in our dataset.

### **Post-hoc Tukey HSD Test**

Post-hoc Tukey HSD comparisons were conducted to identify significant differences in mean energy consumption joules across shipping modes and disruption severity. For Shipping mode, based on the mean differences, the p values are 0.97 between rail and air, 0.973 between road and air, 0.99 between road and rail. For disruption severity, the p value based on mean difference is 0.559. For all the mean differences of pairwise comparisons of disruption severity and shipping modes and in their interaction, there is a significant difference in the mean values but the p values for all the combinations exceed 0.05 and 0.1. (*Please refer figure 26 in Appendix N*),

Hence as the p values are not significant at 1%, 5%, 10% level of confidence we fail to reject the null hypothesis meaning that there is no statistical significance of energy consumption joules on shipping modes, disruption severity and on their interaction.

### **Chi- Square test:**

#### **Two Way Chi- Square Test for Disruption severity and Product Category**

**Alternative Hypothesis (H<sub>1</sub>): Disruption severity depends on product category.**

**Null hypothesis (H<sub>0</sub>): Disruption severity is not dependent on product category.**

The Chi-square test of independence was conducted using R Studio version 4.5.1 to determine the relationship between Product Category and Disruption Severity. The Chi-square test results showed the values as  $\chi^2 = 7.3044$ , degrees of freedom=12 and p value of 0.8368 (*please refer figure 27, in Appendix O*), Based on these results we conclude that at 1%, 5% and 10% level of significance there is no statistically significant dependency between Product Category and Disruption severity meaning that the distribution of disruption severity does not depend on type of product. The disruptions seem to occur similarly across all product categories.

### **Linear Regression**

**Alternate Hypothesis(H<sub>1</sub>):** Quantity Ordered does have a linear effect on Order Value USD

**Null Hypothesis(H<sub>0</sub>):** Quantity Ordered does not have a linear effect on Order Value USD

Simple linear regression was performed using R Studio version 4.5.1 on Quantity ordered and Order value to know the effect of Quantity ordered on the Order value. From figure 15, The predictor Quantity Ordered is not statistically significant, as evidenced by its p-value of 0.492, which exceeds all conventional significance thresholds (1%, 5%, and 10%). Because the predictor is not significant at any of these levels, it provides no meaningful explanatory power for the dependent variable, accounting for only 0.047% of the variation in Order Value USD. As a result, the overall regression model is also not statistically significant, indicating that the model does not reliably explain variation in the outcome. This outcome reflects a very weak linear association, demonstrating that Quantity Ordered does not exert a meaningful linear influence on Order Value USD in this dataset. (*Please refer figure 28, in Appendix P*),

### **Multi Linear Regression**

**Multi Linear Regression for Order Value, Quantity Ordered, Historical Disruption Count, Supplier Reliability Score and Communication Cost:**

**Alternative Hypothesis (H<sub>1</sub>):** Quantity Ordered, Historical Disruption Count, Supplier Reliability Score, Communication Cost has significant linear effect on Order Value

**Null Hypothesis (H<sub>0</sub>):** Quantity Ordered, Historical Disruption Count, Supplier Reliability Score, Communication Cost has no significant linear effect on Order Value

**Multi Linear Regression Equation:**

$$\text{Order Value} = \beta_0 + \beta_1(\text{Quantity Ordered}) + \beta_2(\text{Historical Disruption Count}) + \beta_3(\text{Supplier Reliability Score}) + \beta_4(\text{Communication Cost}) + \epsilon$$

These coefficients quantify the relationship between each predictor and the target variable, which is the **Order Value**. The tests were performed using R Studio version 4.5.1. The multi linear regression test returned p-value for **Quantity Ordered** is 0.429, which is not significant at 5%, 10% and at 1%. This provides enough evidence to support quantity ordered does not have a linear relationship with Order Value at all significant levels.

Secondly, the **Historical Disruption Count** is 0.784, which is not significant at 1%, 5%, 10%. This proves there is not enough evidence to support that historical disruption count has a linear relationship with Order value. Likewise, the p-value for **Supplier Reliability Score** is 0.385, which is not significant at 1%, 5%, 10%. This proves there is not enough evidence to support the Supplier Reliability Score having a linear relationship with Order Value. Finally, the p-value for **Communication Cost** is 0.171, which is not significant at 1%, 5%, and 10%. This proves there is not enough evidence to support the Communication Cost having a linear relationship with Order Value.

From the above testing we conclude, Order Value is driven by factors NOT included in this model. Selected predictors do not statistically explain variation in order value.

From the adjusted R-squared value given in *Figure 30 in Appendix P* shows that only 0.07% of the variation in Order value is explained by the predictors variables such as Quantity Ordered, Historical Disruption Count, Supplier Reliability Score and Communication Cost, proposing that the model has very less predictive power.

**Linear Regression Coefficients:**

**Intercept (28313.534):** This is the expected value of the Order Value when all the predictor variables are zero. This serves as the baseline from which the effect of each predictor variable is measured. **Quantity Ordered (1.222).** For each additional unit of quantity ordered, the order value is expected to increase by 1.222, assuming all other variables remain constant. **Historical**

**Disruption Count (-22.058)** This negative coefficient suggests that for every unit increase of the historical disruption count, there is a decrease in the order value by 22.058, while all other variables remain constant. **Supplier Reliability Score (-2767.892)** The negative coefficient in the given scenario shows that for every unit increase in the supplier reliability score, there is an expected decrease of 2767.892 in order value, keeping other variables constant. **Communication Cost (-490.660)** From this negative coefficient here, we understand that for every unit increase in the communication cost, there is an expected decrease of 490.660 in order value, while assuming other variables constant.

The variance inflation factor (VIF) values for all predictors are approximately 1 (*please refer to Figure 31, in appendix P*), indicating no multicollinearity exists among all the predictor variables such as Quantity Ordered, Historical Disruption Count, Supplier Reliability Score and Communication Cost. This suggests that the predictors are independent of each other and do not misshape the linear regression estimates.

## Conclusion

This study presents a detailed analysis of U.S. supply chain performance serving 1,000 real-world–simulated transactional records. Results across a number of hypothesis tests and models consistently indicate that major operational variables (e.g., shipping mode, disruption severity, supplier reliability, order size) have no statistically significant impact on order value, energy usage, and shipment reliability. In some cases, there were differences in means but these differences were due to chance rather than any meaningful structural difference. The regression models had very low R-squared values, suggesting that the variables in this dataset do not capture what primarily determines the value and risk of a shipment.

Yet, the descriptive results portray a system in which risk abounds, empirically observed disruptions are not so frequent, and these disruptions are fairly evenly spread across product categories. The high amount of supplier data sharing also implies that there is significant scope for collaborative analytics and federated learning solutions. Taken together, these findings provide further support for the investigation of additional levels of data granularity, including other operational, environmental, or contractual considerations that may enhance predictiveness in subsequent supply chain risk analyses. For practitioners and defence logistics organizations, the research demonstrates the necessity of prioritizing systemic drivers of performance over

isolated operational measures in constructing resilient and adaptive supply chain strategies.

Upon further analysis of data through hypothesis testing and carrying out tests taught in the class, it is evident that the dataset does not establish any significant relationships between any variable. Only the Z test proved a weak significance between the population and sample mean of the order value and the Electronic product at the 5% and 10% thresholds. However, the other tests have proved to be consistently insignificant which implied that there is a lack of correlation or causation present between the numerical and categorical variable present in the dataset. Although logically disruption severity could be dependent on the shipping mode at time, our dataset lacked the statistical evidence to prove the hypothesis.

Regression models on the other hand, we were unable to provide any meaningful predictors for the Order Value variable in both simple and multiple linearity models. The absence of multicollinearity between the variables could best explain the lack of statistical evidence to prove all or any relationships at all. Overall, we have observed that our dataset signals were weak thereby limiting statistical evidence to prove any of our rational and logical hypothesis.

**Recommendations:** There is a scope for further analysis of the US supply chain risk management, provided there is an immense increase in the variability of the dataset and the integration of a product category partitioned using the help of a stock keeping unit (SKU) variable. Thus concluding, although the data pertains to the real world, the data set could be improved with many more variables and rows to analyze existing correlations through hypothesis testing and conducting unbiased predictive analysis.

## Appendices

### Appendix A. Description of all the variables in the dataset

**Order\_ID:** 1000 Unique identifier for each shipment/transaction.

**Buyer\_ID:** 50 Unique identifier for the buyer making the order.

**Supplier\_ID:** 30 Unique identifier for the supplier fulfilling the order.

**Product\_Category:** Category of product (eg. Electronics, Food, Textiles).

**Quantity\_Ordered:** Number of units ordered in the transaction.

**Order\_Date:** Date when the order was placed.

**Dispatch\_Date:** Date when the order was shipped.

**Delivery\_Date:** Date when the order was delivered.

**Shipping\_Mode:** Method of shipment (Air, Sea, Road, Rail).

**Order\_Value\_USD:** Value of the order in U.S. dollars.

**Delay\_Days:** Number of days late compared to planned delivery.

**Disruption\_Type:** Type of disruption (eg. Weather, Strike, Equipment).

**Disruption\_Severity:** Severity level of disruption (Low, Medium, High).

**Historical\_Disruption\_Count:** Number of past disruptions for the supplier.

**Supplier\_Reliability\_Score:** Score (0–1) showing how reliable the supplier is.

**Organization\_ID :** 20 Unique identifier for the organization involved.

**Dominant\_Buyer\_Flag:** Binary indicator (0/1) if a buyer is dominant for supplier.

**Available\_Historical\_Records:** previous historical records between supplier & buyer.

**Data\_Sharing\_Consent:** Binary indicator (0/1) if supplier consents to share data.

**Federated Round:** Iteration or training round number in a federated learning process for Supply chain optimization.

**Parameter\_Change\_Magnitude:** Amount of change in model parameters.

**Communication\_Cost\_MB:** Amount of communication data used (megabytes).

**Energy\_Consumption\_Joules:** Energy used to process/transport the shipment (joules).

**Supply\_Risk\_Flag** – Binary indicator determining if a shipment is risky or not.

**Appendix B. Shipping Mode Positioning based on Order Value and Quantity  
ordered**

| <b>Row Labels</b>  | <b>Sum of<br/>Order Value USD</b> | <b>Sum of<br/>Quantity Ordered</b> |
